## **Abstract**

TSP algorithms by Maciej Woczyk.  
In this document we'll see how Brute Force and Nearest Neighbor solutions behave with certain maps of cities.

Figure 1: As we can see in this example brute force is much more efficient. Nearest Neighbor starts with town #1, goes to the closest #2, then #3 and #4, making unnecessarily long comeback to #1. Brute Solution often goes on the "edge" of our town map, since going through the center would mean coming a long way back.

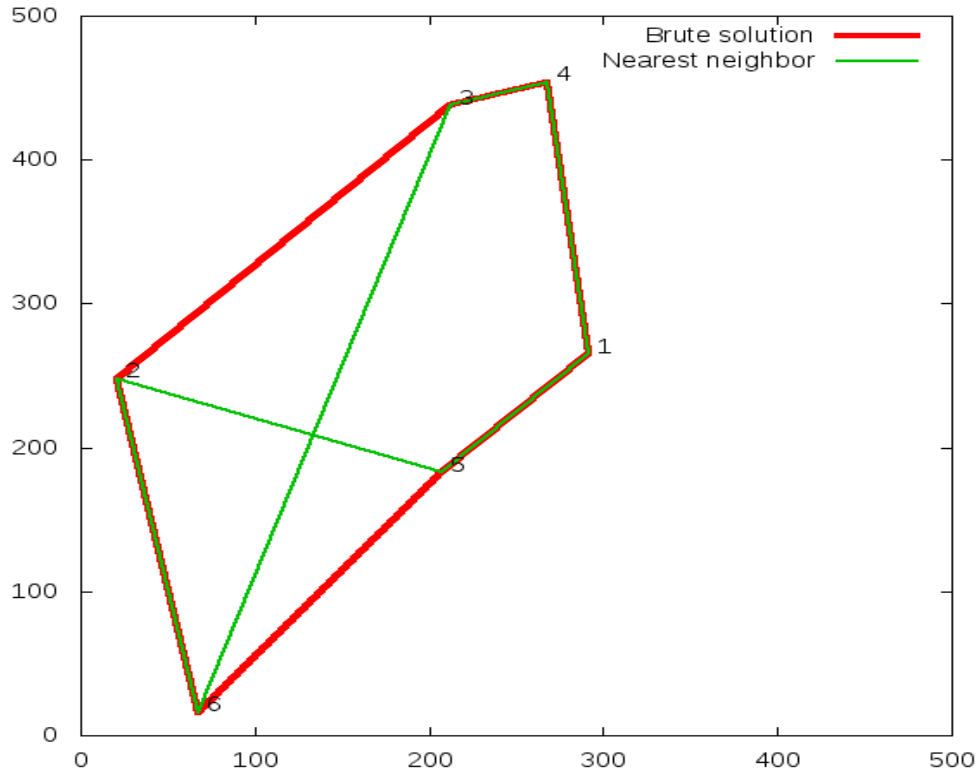

Figure 2: The more the points, the worse Nearest Neighbor behaves. As we can see, routes of both algorithms are the same at the beginning  $\#3 \Rightarrow \#4 \Rightarrow \#1 \Rightarrow \#5$  but then Nearest Neighbor takes the worse path to  $\#2$  instead of  $\#6$ . That means it has to go unnecessarily long way to get back to  $\#3$ .

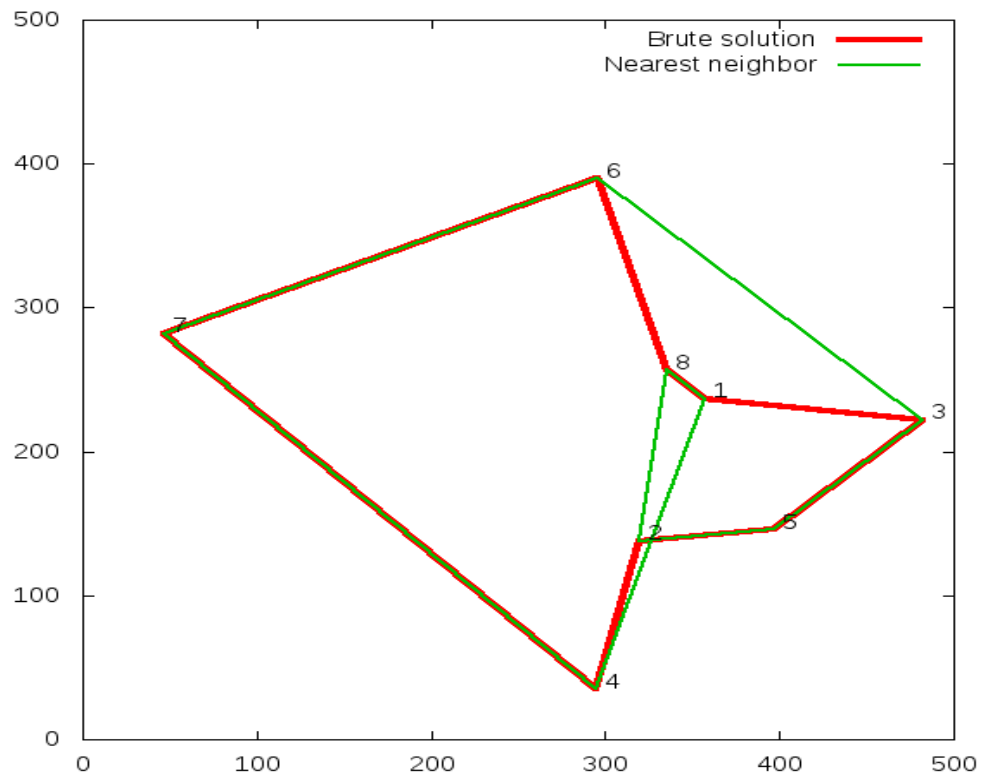

Figure 3: With 8 points routes become more complicated. Brute solution keeps going on the edge of our map, but nearest neighbor takes some wrong turns (i.e. #6  $\Rightarrow$  #3)

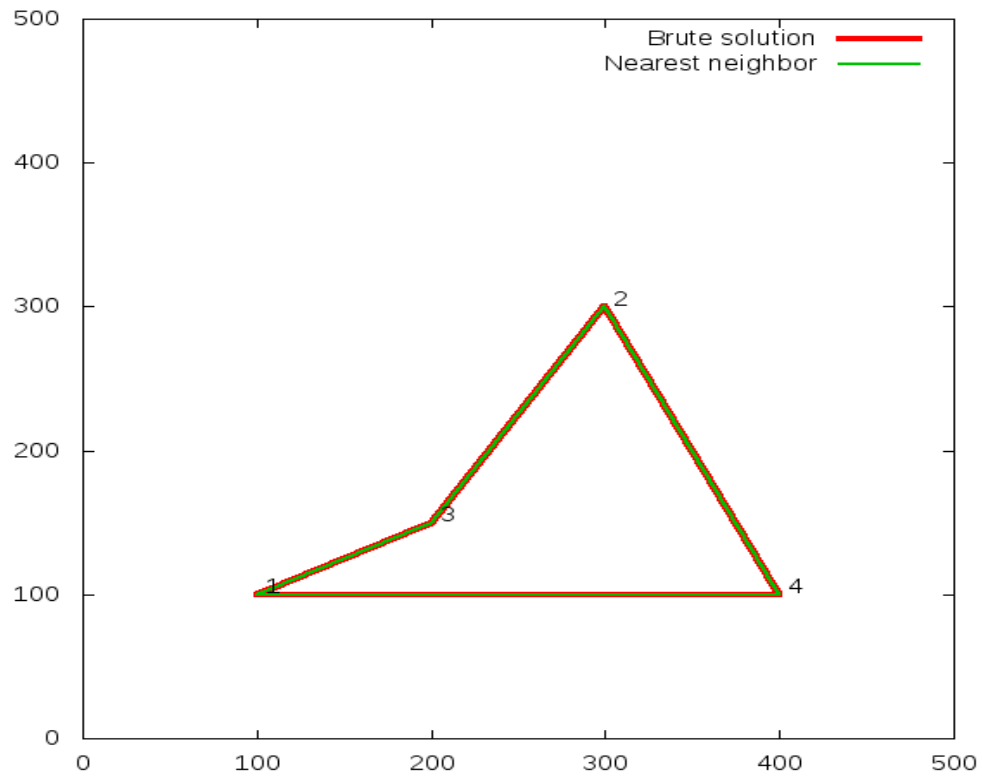

Figure 4: A straightforward example, showing that with simple town placement Nearest Neighbor manages to keep up with the best solution produced by brute forcing.

Figure 5: But if distances between towns are a little bit more tricky, Nearest Neighbor makes some mistakes. The main advantage of this algorithm is that it is relatively quick - with  $O(n^2)$  complexity. In comparison, brute force solution is  $O(n!)$  complex. Since TSP is NP-hard, there is probably no algorithm which gives precise, exact solution faster than  $O(2^n)$ .
